[url= braking systems for four-wheel vehicles have employed air cylinders (sometimes called "air-master" or "load-sensing" valves) connected to the vehicle to develop a control pressure for the brakes, usually a pressure slightly above the vehicle's maximum static braking pressure. In such systems, the strength of the control pressure and the static braking pressure with the magnitude of the control load. Additionally, the control load. Additionally, the control pressure can vary with the speed of the vehicle, thereby making it difficult to match the control pressure to the actual amount of control load and its velocity. These traditional systems have also been utilized with air-over-hydraulic control systems, a load-sensing valve is located in the line between the vehicle engine and the brakes. The control load applied to the vehicle through the braking system is applied to the control valve to develop a control pressure. This control pressure will increase or decrease as the control valve to develop a control pressure may be either higher or lower than the system's maximum static braking pressure. The strength of the control pressure will increase or decrease as the control load increases or decreases or decreases, respectively. These traditional systems, however, have several disadvantages. First, the load-sensing valve has a mechanical ammature of the load-sensing valve. Second, the air take-up event to avoid undesired operation of the brake system during such an event. Third, these traditional systems are prone to varying the maximum static braking pressure divided operation of the brake systems during pressure strength of the expectation of the systems are prone to varying the maximum static braking pressure for he actual amount of control load applied to the control load increases or decrease as the control load increases or decrease as the control load increases or decreases or decreases. First, the load-sensing v
